PREFACE

THE tables of the properties of saturated steam which have appeared up to the present time have all been based upon the classic investigations of Regnault, carried out more than sixty years ago. It has been apparent for some time that the total heats of dry and saturated steam, as determined by those admirable researches, are below the correct values. The great difficulty in obtaining steam which is exactly dry and saturated has not been appreciated until very recently; and it is undoubtedly true that Regnault was investigating steam containing a small amount of moisture when he thought that he was dealing with dry steam. Fortunately, the recent investigations of Dieterici, Smith Griffiths, Henning and Joly give a trustworthy body of new values of the total heat of dry steam at pressures below atmospheric pressure; while the method recently elaborated by Davis, when applied to the throttling experiments of Grindley, of Peake, and of Griessmann, gives remarkably accordant determinations at pressures above atmospheric pressure. The table which we have prepared is based entirely upon these new values, and is probably correct to one tenth of one per cent within the range of steam pressures usual in engineering practice. Regnault's formula gives results which are too high by 18 B. t. u. at 32° F.; too low by 6 B. t. u. at 275° F.; and again too high at 380° F.; the error increasing rapidly at higher temperatures.

The investigations of Knoblauch, of Thomas and of Henning are the necessary basis for any determinations of the properties of superheated steam. These investigations have been subjected to a careful analysis, both as to the probable errors resulting from the methods of experimentation, and also as to the relation of the experimental results to the values deduced from thermodynamic theory, so far as this latter throws any light on the matter. Where the results of the separate investigations are not closely accordant, a critical estimate has been made of the relative values to be given to each, in the region under consideration. The properties of superheated steam are tabulated for every pound pressure, and for every ten degrees of superheat, within a range which exceeds present practice. All the information relating to superheated steam of any pressure is given on one double-page; an arrangement which permits the immediate finding of any desired quantity. Supplementary tables extend the superheated steam table to very high temperatures and give the properties of water, metric conversion factors, Naperian logarithms and other quantities.

Beside the tables, we have prepared two large diagrams showing the properties of saturated and superheated steam. These diagrams can be used, instead of the tables, for finding the total heat, entropy and specific volume of steam of any known quality or superheat (within an extended range); but their chief purpose is to facilitate certain calculations. In consequence of the variation of the specific heat of super-

heated steam with both pressure and temperature, the solution of commonly occurring problems involving superheated steam is either laborious or approximate. If the tables are arranged in such a manner as to aid the solution of problems of one class, they become inconvenient for other purposes. The total heat-entropy diagram, devised by Mollier, makes it possible to solve immediately many of the problems which arise in connection with either saturated or superheated steam. A total heat-pressure diagram, showing specific volumes, permits the solution of problems involving volumes. By the use of the two diagrams, either separately or together, a large number of the steam problems occurring in the design of engines and turbines, or in connection with the flow of steam, or its throttling, can be solved without any calculation. These two diagrams have been plotted with great care from the data given in the tables, and should prove useful to all engineers or students engaged in making calculations which involve saturated or superheated steam.

The authors desire to express their indebtedness to Professor E. V. Huntington for the use of the plates of his four-place tables of logarithms, and to Mr. M. R. Wolfard, S. B., for his patient and skilful assistance in the arduous work of computation and in drawing the diagrams.

CAMBRIDGE, MASS., December, 1908.

NOTE TO THE 1916 REPRINT. The experimental information which has become available since these tables were computed does not justify any appreciable change in them except in one respect. The work of Holborn and Baumann * on the pressure-temperature relations of saturated steam at high pressures should apparently be accepted in preference to all previous work. The pressures involved are from 400 lb. per sq. in. to the critical pressure and are consequently outside the range of usual engineering experience. The last few entries in Tables 1, 2, 3, and 6 have been changed to bring them into agreement with this new information.

A new Mollier chart has been prepared which will be found to be more convenient than the earlier Diagram I.

CONTENTS

THE TABLES

OF the three main steam tables, the first and second are for water and saturated steam only, and give explicitly all of the properties that are ordinarily needed. Table 3 is primarily for superheated steam, but includes saturated steam as the special case of zero superheat.

In Table 1, the argument is the temperature. This table is useful for hygrometric and other purposes as well as for steam engineering. To facilitate the handling of condenser vacuums, all pressures below one atmosphere are given in inches of mercury as well as in lbs. per sq. in. The use of this table in accurate calorimetry is made possible by giving the heat of the liquid to hundredths of a mean B. t. u. between 32° and 212°.

The data upon which steam tables must be based are well known only to about 400°. It is, however, often convenient to be able to work roughly at much higher temperatures. Table 1 has, therefore, been extended to the critical point itself, but the values above 400° should not be used with too much confidence (see the discussion of sources in Part III of this book).

In Tables 2 and 3, the argument is the pressure. These tables extend to 600 lbs., the values above 250 lbs. being less certain than those below. Table 3 can be extended to very high superheats by means of Table 4.

There is also a table of boiling points for use in calibrating thermometers, a table of the thermal properties of water, a full set of conversion tables, particularly for energy units, and tables of four-place logarithms, both common and Naperian.

The unit of heat and of energy in these tables is a "mean B. t. u.," that is, 1/180 of the heat needed to raise one pound of water from the freezing to the boiling point. The use of such a unit instead of the B. t. u. at 60° F. corresponds to the rapidly increasing use of the Bunsen or mean calorie in the metric system, and has many advantages, among which is the ease with which tables based on the two mean units can be compared. The most important reason for such a choice in these tables is that, at the present time, the value of the mean unit is better known than that of the 60° unit, because of the rapidity with which the specific heat of water changes with the temperature near 60°. The mean B. t. u. is larger than the 60° B. t. u. by between three and ten *hundredths* of one per cent, a difference that is negligible for engineering purposes.

THE DIAGRAMS

IN order to facilitate the solution of many problems of common occurrence, two large diagrams have been prepared to accompany this book.

The Total Heat-Entropy Diagram (Diagram I) has two families of curves: (*a*) curves of constant pressure, and (*b*) curves of constant quality and constant superheat. The ordinates are total heat (*i. e.* heat of formation measured above water at 32° F.); the abscissæ are entropies. Vertical lines are lines of constant entropy and show the change in the condition of steam during adiabatic expansion. Measurements along vertical lines give the change in the total heat of steam during adiabatic expansion (which is equal to the work done in the Rankine ideal cycle); the same measurements transferred to the velocity scale give the theoretical velocity of escape of steam through a properly shaped orifice or nozzle. Horizontal lines are lines of constant total heat; they show the change in the condition of steam which results from throttling.

The Total Heat-Pressure Diagram (Diagram II) has two families of curves: (*a*) curves of constant specific volume, and (*b*) curves of constant quality and constant superheat. The ordinates are total heats; the abscissæ, pressures. Vertical lines are lines of constant pressure; measurements along vertical lines give the heat supply accompanying changes of volume or quality at constant pressure. Horizontal lines are lines of constant total heat; they show the change of volume and condition of the steam resulting from throttling. The scale of abscissæ is a uniform scale of temperatures of saturated steam, which gives a varying scale of steam pressures. This varying scale has the advantage of spreading out the specific volume curves at low pressures.

The use of total heats as ordinates has certain special advantages. The energy given up by steam that is passing through any appliance is equal to the difference between the total heat of the entering and of the leaving steam. This difference is represented by vertical measurements on the diagram.

The method of using these diagrams for the solution of problems is explained in detail in Part II.

Table 1. Saturated Steam: Temperature Table

* 1 atmo (standard atmosphere) = 760 mms. of Hg. by definition = 29.921 ins. of Hg. = 14.696 lbs. per sq. in.
For water, at 345°(126 lbs.), sp. vol., v′ or σ = 0.0179 cu. ft. per lb.; 1/v′ = 55.8 lbs. per cu. ft.; 144 Apv′ = 0.42 B.t.u.;
at 370°(173 lbs.), v′ or σ = 0.0183 " ; 1/v′ = 54.8 " ; 144 A v′ = 0.59 " .

t is the temperature, in Fahrenheit degrees; h is the total heat, in B. t. u., from water at 32°;
v is the specific volume, in cu. ft. per lb.; n is the entropy, from water at 32°.

t = temperature in F. degs. T° Fahr. absolute = t° + 459.6°. Internal energy
v = sp. vol. in cu. ft. per lb. J = 777.5 ft. lbs. per B. t. u. [log = 2.89 071]. = total heat − 144 Apv.
h = total heat in B. t. u. A = 1/J = 1.286 × 10⁻³ B. t. u. per ft. lb. [3.10 929]. Values for saturated steam
n = entropy. 144 A = 0.1852 [log = 1.26 764]. are given in Tables 1 and 2.

Conversion from Metric Units

1 kg. per sq. cm. = 14.22 lbs. per sq. in. [log = 1.15 300]. 1 cu. meter = 35.31 cu. ft. [log = 1.54 795].
To change degs. C. to degs. F., multiply by $\frac{9}{5}$, and add 32. To change mean kg. calories per kg. to mean B.t.u. per lb., multiply by $\frac{9}{5}$. Entropy same in both systems.

Table 3: Superheated Steam

t = temperature in F. degs. T° Fahr. absolute = t° + 459.6°. Internal energy
v = sp. vol. in cu. ft. per lb. J = 777.5 ft. lbs. per B.t.u. [log = 2.89 071]. = total heat − 144 Apv.
h = total heat in B.t.u. A = 1/J = 1.286 × 10⁻³ B.t.u. per ft. lb. [3.10 929]. Values for saturated steam
n = entropy. 144 A = 0.1852 [log = $\bar{1}$.26 764]. are given in Tables 1 and 2.

Conversion from Metric Units

1 kg. per sq. cm. = 14.22 lbs. per sq. in. [log = 1.15 300]. 1 cu. meter = 35.31 cu. ft. [log = 1.54 795].
To change degs. C. to degs. F., multiply by $\frac{9}{5}$, and add 32. To change mean kg. calories per kg. to mean B.t.u. per lb., multiply by $\frac{9}{5}$. Entropy same in both systems.

Table 3: Superheated Steam

t = temperature in F. degs. T° Fahr. absolute = t° + 459.6°. Internal energy
v = sp. vol. in cu. ft. per lb. J = 777.5 ft. lbs. per B.t.u. [log = 2.89 071]. = total heat − 144 Apv.
h = total heat in B.t.u. A = 1/J = 1.286 × 10⁻³ B.t.u. per ft. lb. [3.10 929]. Values for saturated steam
n = entropy. 144 A = 0.1852 [log = $\bar{1}$.26 764]. are given in Tables 1 and 2.

Conversion from Metric Units

1 kg. per sq. cm. = 14.22 lbs. per sq. in. [log = 1.15 300]. 1 cu. meter = 35.31 cu. ft. [log = 1.54 795]. To change degs. C. to degs. F., multiply by $\frac{9}{5}$, and add 32. To change mean kg. calories per kg. to mean B.t.u. per lb., multiply by $\frac{9}{5}$. Entropy same in both systems.

t = temperature in F. degs. T° Fahr. absolute = t° + 459.6°. Internal energy
v = sp. vol. in cu. ft. per lb. J = 777.5 ft. lbs. per B.t.u. [log = 2.89 071]. = total heat − 144 Apv.
h = total heat in B.t.u. A = 1/J = 1.286 × 10⁻³ B.t.u. per ft. lb. [3.10 929]. Values for saturated steam
n = entropy. 144 A = 0.1852 [log = $\bar{1}$.26 764]. are given in Tables 1 and 2.

Conversion from Metric Units

1 kg. per sq. cm. = 14.22 lbs. per sq. in. [log = 1.15 300]. 1 cu. meter = 35.31 cu. ft. [log = 1.54 795].
To change degs. C. to degs. F., multiply by $\frac{9}{5}$, and add 32. To change mean kg. calories per kg. to mean B.t.u. per lb., multiply by $\frac{9}{5}$. Entropy same in both systems.

Table 3 — Superheated Steam

t = temperature in F. degs. T° Fahr. absolute = t° + 459.6°. Internal energy
v = sp. vol. in cu. ft. per lb. J = 777.5 ft. lbs. per B.t.u. [log = 2.89 071]. = total heat − 144 Apv.
h = total heat in B.t.u. A = 1/J = 1.286 × 10⁻³ B.t.u. per ft. lb. [3.10 929]. Values for saturated steam
n = entropy. 144 A = 0.1852 [log = $\bar{1}$.26 764]. are given in Tables 1 and 2.

Conversion from Metric Units

1 kg. per sq. cm. = 14.22 lbs. per sq. in. [log = 1.15 300]. 1 cu. meter = 35.31 cu. ft. [log = 1.54 795]. To change degs. C. to degs. F., multiply by 9/5 and add 32. To change mean kg. calories per kg. to mean B.t.u. per lb., multiply by 9/5. Entropy same in both systems.

Table 3: Superheated Steam

t = temperature in F. degs. T° Fahr. absolute = t° + 459.6°.
v = sp. vol. in cu. ft. per lb. J = 777.5 ft. lbs. per B.t.u. [log = 2.89 071].
h = total heat in B.t.u. A = 1/J = 1.286 × 10⁻³ B.t.u. per ft. lb. [3.10 929].
n = entropy. 144 A = 0.1852 [log = 1.26 764].

Internal energy = total heat − 144 Apv.
Values for saturated steam are given in Tables 1 and 2.

Conversion from Metric Units

1 kg. per sq. cm. = 14.22 lbs. per sq. in. [log = 1.15 300]. 1 cu. meter = 35.31 cu. ft. [log = 1.54 795].
To change degs. C. to degs. F., multiply by $\frac{9}{5}$, and add 32. To change mean kg. calories per kg. to mean B.t.u. per lb., multiply by $\frac{9}{5}$. Entropy same in both systems.

t = temperature in F. degs. T° Fahr. absolute = t° + 459.6°.
v = sp. vol. in cu. ft. per lb. J = 777.5 ft. lbs. per B. t. u. [log = 2.89 071].
h = total heat in B. t. u. A = 1/J = 1.286 × 10⁻³ B. t. u. per ft. lb. [3.10 929].
n = entropy. 144 A = 0.1852 [log = 1.26 764].

Internal energy = total heat − 144 Apv. Values for saturated steam are given in Tables 1 and 2.

Conversion from Metric Units

1 kg. per sq. cm. = 14.22 lbs. per sq. in. [log = 1.15 300]. 1 cu. meter = 35.31 cu. ft. [log = 1.54 795].
To change degs. C. to degs. F., multiply by $\frac{9}{5}$, and add 32. To change mean kg. calories per kg. to mean B.t.u. per lb., multiply by $\frac{9}{5}$. Entropy same in both systems.

Table 3. Superheated Steam

t = temperature in F. degs. T° Fahr. absolute = t° + 459.6°. Internal energy
v = sp. vol. in cu. ft. per lb. J = 777.5 ft. lbs. per B. t. u. [log = 2.89 071]. = total heat − 144 Apv.
h = total heat in B. t. u. A = 1/J = 1.286 × 10⁻³ B. t. u. per ft. lb. [3.10 929]. Values for saturated steam
n = entropy. 144 A = 0.1852 [log = 1.26 764]. are given in Tables 1 and 2.

Conversion from Metric Units

1 kg. per sq. cm. = 14.22 lbs. per sq. in. [log = 1.15 300]. 1 cu. meter = 35.31 cu. ft. [log = 1.54 795].
To change degs. C. to degs. F., multiply by $\frac{9}{5}$, and add 32. To change mean kg. calories per kg. to mean B.t.u. per lb., multiply by $\frac{9}{5}$. Entropy same in both systems.

Table 3: Superheated Steam

t = temperature in F. degs. T° Fahr. absolute = t° + 459.6°.
v = sp. vol. in cu. ft. per lb. J = 777.5 ft. lbs. per B.t.u. [log = 2.89 071].
h = total heat in B.t.u. A = 1/J = 1.286 × 10⁻³ B.t.u. per ft. lb. [3.10 929].
n = entropy. 144 A = 0.1852 [log = 1.26 764].

Internal energy = total heat − 144 Apv.
Values for saturated steam are given in Tables 1 and 2.

Conversion from Metric Units

1 kg. per sq. cm. = 14.22 lbs. per sq. in. [log = 1.15 300]. 1 cu. meter = 35.31 cu. ft. [log = 1.54 795].
To change degs. C. to degs. F., multiply by 9, and add 32. To change mean kg. calories per kg. to mean B.t.u. per lb., multiply by 9. Entropy same in both systems.

Table 3: Superheated Steam

t = temperature in F. degs. T° Fahr. absolute = t° + 459.6°.
v = sp. vol. in cu. ft. per lb. J = 777.5 ft. lbs. per B. t. u. [log = 2.89 071].
h = total heat in B. t. u. A = 1/J = 1.286 × 10⁻³ B. t. u. per ft. lb. [3.10 929].
n = entropy. 144 A = 0.1852 [log = 1.26 764].

Internal energy = total heat − 144 Apv.
Values for saturated steam are given in Tables 1 and 2.

Conversion from Metric Units

1 kg. per sq. cm. = 14.22 lbs. per sq. in. [log = 1.15 300]. 1 cu. meter = 35.31 cu. ft. [log = 1.54 795].
To change degs. C. to degs. F., multiply by $\frac{9}{5}$, and add 32. To change mean kg. calories per kg. to mean B.t.u. per lb., multiply by $\frac{9}{5}$. Entropy same in both systems.

Table 3: Superheated Steam

Press. lbs.		Water	Sat. Steam	Degrees of Superheat 10°	20°	30°	40°	50°	60°	70°	80°	90°	100°	110°	120°

This table gives, either directly or by interpolation, the excess of the total heat or entropy at any given pressure and superheat above that at the same pressure and 600° superheat. The actual total heat or entropy is obtained by adding this increment to the corresponding value in the 600° column of Table 3.

Power

1 horse power (H. P.) is 550 ft. lbs. per second. 1 watt is 1 Joule per second or 10^{7} ergs per second. 1 kilowatt (K. W.) is 1000 watts. 1 cheval-vapeur, or pferdekraft, or "continental horse power," is 75 kg. meters per second. 1 poncelet is 100 kg. meters per second.

1 K. W.	=	1.3410	H. P.,	log =	0.12 743	1 H. P.	=	0.7457	K. W., log = $\bar{1}$.87 257

Logarithms to the Base 10

These two pages give the common logarithms of numbers between 1 and 10, correct to four places. Moving the decimal point n places to the right (or left) in the number is equivalent to adding n (or $-n$) to the logarithm. Thus, $\log 0.017453 = 0.2419 - 2 \; [= \bar{2}.2419]$.

To facilitate interpolation, the tenths of the tabular differences are given at the end of each line, so that the differences themselves need not be considered. In using these aids, first find the nearest tabular entry, and then add (to move to the right) or subtract (to move to the left), as the case may require.

Pages 72-77 are reprinted by permission, with unimportant changes, from Huntington's "Four Place Tables."

Logarithms to the Base e

These two pages give the natural (hyperbolic, or Napierian) logarithms of numbers between 1 and 10, correct to four places. Moving the decimal point n places to the right (or left) in the number is equivalent to adding n times 2.3026 (or n times $\bar{3}.6974$) to the logarithm.

1	2.3026	1	0.6974 − 3
2	4.6052	2	0.3948 − 5
3	6.9078	3	0.0922 − 7
4	9.2103	4	0.7897 − 10
5	11.5129	5	0.4871 − 12
6	13.8155	6	0.1845 − 14
7	16.1181	7	0.8819 − 17
8	18.4207	8	0.5793 − 19
9	20.7233	9	0.2767 − 21

PART II

THE USE OF THE DIAGRAMS

THE steam tables give values of the simultaneous physical coördinates (or properties) of steam, such as the pressure, specific volume, temperature, entropy, total heat, and internal energy. When certain of these physical coördinates are known, the remainder can be obtained from the tables, either directly, or by an interpolation. The values tabulated are for dry and saturated steam and for superheated steam; if the steam is wet, its properties must be calculated.

The simultaneous properties of steam can also be shown by the use of a steam diagram. The diagram may be drawn on a plane which has any independent pair of the properties as its coördinates; for example, the ordinates and abscissæ may be, respectively, pressures and specific volumes, or temperatures and entropies, or total heats and entropies, or total heats and pressures. Each point on such a plane represents steam in a perfectly definite condition: that is, with all its physical coördinates fixed. On such a plane it is possible to plot a steam diagram, or chart, consisting of a number of curves, each of which goes through all points on the plane having a certain constant value of some one physical coördinate. If a well-selected and sufficient number of such curves is drawn for each physical coördinate, then, for any point on the plane, all the properties of steam can be determined by reading the corresponding ordinate and abscissa, and by interpolation in the plotted families of curves. For example, on a pressure-volume plane on which families of constant entropy curves, and of constant total heat curves, are drawn, there can be read off by inspection the pressure, volume, entropy, and total heat, corresponding to any point on the plane.

The families of curves which are drawn may include curves of constant dryness factor (quality) of saturated steam; consequently the diagram may give by inspection the properties of wet steam. This is an advantage over the tables.

Of the various planes on which these diagrams may be drawn, some are more convenient than others. Any one of them will serve if the only purpose in view is to find single values of physical coördinates. For this purpose, the relative advantages of the various planes is a question only of the accuracy and ease with which the desired quantities can be read.

A diagram may, however, have uses other than merely showing the simultaneous properties of steam. It may be used for the solution of certain problems, if the proper plane is chosen and the necessary families of curves are drawn on it. It should be clearly borne in mind that the choice of a plane for this purpose has no relation to the choice of a plane on which to represent the cycle of operations of a steam

engine or other steam appliance. For the latter purpose two special planes are of particular value, (1) the pressure-volume plane, and (2) the temperature-entropy plane. The pressure-volume plane shows the amount of external work done while the steam is going through any series of changes; the temperature-entropy plane, in a similar way, shows the heat added to or abstracted from the steam. To find the work done or the heat exchange, it is only necessary that the steam cycle should be drawn on those planes; the presence of families of curves of the physical co-ordinates is of no use in finding those quantities. In other words, the plane alone is required for that purpose, not a steam diagram on that plane.

A steam diagram on the pressure-volume plane, or on the temperature-entropy plane, does not offer any particular advantages over other diagrams for finding steam quantities. For the solution of many problems of common occurrence such a diagram is decidedly less useful and convenient than a diagram in which the total heat of steam is one of the coördinates.

By the total heat of steam is meant the sum of its internal energy, E, and of the heat equivalent of the product of its pressure and specific volume, or

$$H = E + 144\ Apv.$$

(It should be noted that total heat defined in this way differs slightly from the total heat as found in Regnault's investigations of saturated steam and as usually given in steam tables; for a discussion of this, see page 101.)

The total heat of steam is a quantity which enters into a large number of problems. It represents the energy (other than kinetic energy) entering any piece of apparatus with every pound of steam that goes to it, and the energy (other than kinetic) leaving it with every pound of steam that leaves it. In most steam appliances, under steady conditions of operation, the weight of steam entering per unit of time is equal to the weight of steam leaving. In such an appliance if H_1 is the total heat of one pound of the entering steam, and H_2 is the total heat of one pound of the leaving steam, then $H_1 - H_2$ is the energy given up in the apparatus by each pound of steam. In a steam engine $H_1 - H_2$ is the sum of the work done and of the external heat-losses; in a boiler its value is negative and represents the heat supply per pound of steam formed; in a non-conducting steam nozzle it is the heat that is converted into kinetic energy; in a throttling calorimeter its value is zero because there is no external work done, no heat conduction, and no change in kinetic energy.

On a steam diagram on which the ordinates are total heats, the quantity $H_1 - H_2$ is represented by the vertical drop between the points representing the entering and leaving conditions. Vertical distances measure the energy given up in a steam appliance, with a constant scale all over the diagram. In flow of steam problems, this constancy of scale permits the immediate graphical determination of the velocity of flow by merely transferring the vertical distance $H_1 - H_2$ to a velocity scale at the side of the diagram. It is in this respect especially that a total heat-entropy diagram is greatly superior to a temperature-entropy diagram.

THE USE OF THE DIAGRAMS

Two diagrams are presented, both with total heats as ordinates. By the superposition of three families of curves it would have been possible to give all the data on one diagram; but that would have led to confusion if the curves had been as closely spaced as is requisite for accurate interpolation.

The diagrams give information as to the total heat, entropy, and specific volume of wet and of superheated steam, within a pressure range from .5 to 600 lbs. per sq. in., and for steam in any condition between a quality of about .7 and a superheat of about 600° F. If the properties of water or the latent heat of steam come into the problem, the tables must be used to supplement the readings from the diagrams.

The principal advantages of the diagrams over the tables are that they give the properties of wet steam, and that they permit an expeditious solution of many problems without calculation and with a degree of accuracy[1] which is sufficient for the ordinary purposes of the engineer.

The method of solution of some of the more commonly occurring problems is given below.

Properties of Steam

The two diagrams give the values of five of the physical coördinates of steam: pressure, quality,[2] entropy, total heat, and specific volume. If any two of these coördinates are known, the remaining three can be found by inspection. In some cases it will be more expeditious (and it will always be more accurate) to use the tables instead of the diagrams, but in other cases, as when wet steam is used, the diagrams will save time and calculation. Pressures, qualities, and total heats can be found on both diagrams; if entropy is involved, Diagram I must be used; if specific volume is involved, Diagram II must be used. The pressure scale on the top of Diagram II is more open than the pressure scale of Diagram I, and consequently somewhat greater accuracy is obtainable by using Diagram II in cases where either diagram can be used.

The method of finding a desired quantity is the same in all cases. The point of intersection of the lines (actual or interpolated) representing the two known quantities is located on the appropriate diagram; the position of this point with reference to the lines representing the desired quantity determines the actual value of that quantity.

Examples.

1. A vessel of 4 cu. ft. capacity contains 0.2 lbs. of water and 0.8 lbs. of steam. What is the pressure?

[1] The accuracy of a two-color diagram depends on the accuracy of registration of the two printings. The original drawings showed in no place an error of as much as $\frac{1}{50}$ inch. The photographic reproduction of these drawings has resulted in minor local distortions, which in the lower corners of Diagram II amount to $\frac{1}{20}$ inch. This is the maximum distortion, and it occurs in the least important part of the diagram.

[2] In what follows, the word *quality* means, the dryness factor if the steam is saturated, the number of degrees of superheat if the steam is superheated. Pressures, throughout, are absolute pressures.

The intersection of the steam quality line, .80, with the specific volume line, 4 cu. ft., on Diagram II, occurs at a steam pressure of 87 lbs. per sq. in. abs.

2. Measurements from an indicator card show that at a certain instant during expansion the volume of the steam is 1.6 cu. ft. and the pressure 40 lbs. per sq. in. abs. If the weight of steam in the cylinder is 0.20 lbs., what is the quality of the steam at that instant?

The specific volume of the steam is $\frac{1.6}{.20}=8$ cu. ft. From Diagram II, steam of that volume and of 40 lbs. pressure has a quality of .764.

3. What is the entropy of 1 lb. of steam at 100 lbs. pressure and a temperature of 450° F.?

From the table on Diagram I, the temperature of saturated steam at 100 lbs. pressure is seen to be 328° F.; the steam is consequently superheated $450-328=122°$ F. From Diagram I, steam at 100 lbs. pressure, superheated 122° F., has an entropy 1.678.

4. An indicator (pressure-volume) card is to be redrawn on the temperature-entropy plane. What are the temperature and entropy corresponding to the condition defined in example 2?

Steam at 40 lbs. pressure has a temperature of 267° F., or $267+460=727°$ abs.

The entropy is seen, by Diagram I, to be 1.373.

5. What is the heat supply per lb. of steam to a boiler with feed water at 100° F., generating steam at 160 lbs. pressure and of a quality .99?

The total heat of steam (Diagram II) at 160 lbs. pressure and quality .99 is 1186 B. t. u.; the feed water contains approximately $100-32=68$ B. t. u. The heat supply per lb. of steam is consequently $1186-68=1118$ B. t. u.

6. What is the volume of 5 lbs. of steam at 1 lb. pressure and a quality .80?

The specific volume (Diagram II) is 265 cu. ft.; the volume of 5 lbs. is consequently $5\times 266=1330$ cu. ft.

Internal Energy

The internal energy of steam of known pressure, p, and specific volume, v, is given by the equation

$$E=H-144\ Apv.$$

Example 7. A cylinder contains 1 lb. of steam at a pressure of 80 lbs. per sq. in. and occupying a volume of 7 cu. ft. What is the internal energy of the steam?

The total heat of the steam (Diagram II) is 1274 B. t. u. The internal energy is

$$1274-.1852\times 80\times 7=1170 \text{ B. t. u.}$$

Adiabatic Expansion

During adiabatic expansion, entropy is constant. Vertical lines on Diagram I are lines of constant entropy. A vertical line is consequently the locus of the points representing the condition of steam which is expanding adiabatically. Two of the three quantities, pressure, specific volume, and quality, will generally be known at some one point on the adiabatic curve; this suffices for finding the entropy. When the entropy and one other property of the steam are known, the condition of the steam is fixed.

To find the quality of steam which has expanded adiabatically to some *known pressure*, locate the intersection of the known entropy and pressure lines; its position with reference to the constant quality lines gives the desired quality.

Example 8. Steam at 120 lbs. pressure, superheated 100° F., expands adiabatically. Find its quality and the ratio of expansion when the pressure reaches 15 lbs. per sq. in.

The entropy of the steam (Diagram I) is 1.651; at 15 lbs. pressure, steam of the same entropy has a quality .928. The initial volume (Diagram II) was 4.33 cu. ft.; the final volume is 24.4 cu. ft. The ratio of expansion is

$$\frac{24.4}{4.33}=5.63.$$

To find the pressure of steam which has expanded adiabatically to a *known quality*, locate the intersection of the known entropy and quality lines. The desired pressure is given by the position of the intersection with reference to the constant pressure lines.

Example 9. Steam at a pressure of 150 lbs. per sq. in., superheated 60° F., expands adiabatically. At what pressure will the steam become dry and saturated?

The entropy (Diagram I) is 1.6105; the corresponding entropy line crosses the dry and saturated steam line at 90 lbs. pressure.

To find the pressure and quality of steam which has expanded adiabatically to a *known volume*, requires the use of both diagrams. The desired pressure and quality lie on the known constant entropy line of Diagram I, and on the known constant specific volume line of Diagram II. Find by inspection of the two diagrams the one pair of simultaneous values of pressure and quality which are common to both lines; or, assume various final pressures, find the corresponding final volumes, and interpolate.

Example 10. Steam of 140 lbs. pressure, superheated 120° F., expands adiabatically with a ratio of expansion of 6. What are the pressure and quality at the end of expansion?

The initial specific volume (Diagram II) is 3.85 cu. ft.; the final specific volume is $6\times 3.85=23.10$ cu. ft. The entropy (Diagram I) is 1.6503. With

this entropy, steam at 17 lbs. has a quality .934 corresponding to a volume of 21.8 cu. ft.; at 15 lbs. the quality is .927, and volume 24.4. The final pressure is evidently between 15 and 17 lbs. At 16 lbs. the quality is .931 and volume 23.0. By interpolation the desired pressure is 15.9 lbs. per sq. in., and the corresponding quality .930.

Work done during Adiabatic Expansion

The work done during adiabatic expansion cannot be taken directly from the diagrams. It is equal in amount but opposite in sign to the change of internal energy during expansion.

$$W_{12}=E_1-E_2=H_1-H_2-144\,A(p_1v_1-p_2v_2)$$

The simplest way of obtaining the work done from the diagrams is to find $H_1—H_2$ for adiabatic expansion, and to subtract from it the second term in the equation given.

Example 11. How much work is done on unit mass of steam at 15 lbs. pressure and quality .90 when it is compressed adiabatically to one-fourth its original volume?

By a process similar to that given in example 10, the pressure at the end of compression is found to be 72 lbs. per sq. in., and the corresponding quality .988. The volumes at the beginning and end of the compression are 23.62 and 5.905 cu. ft. respectively.

The work done by the steam is

$$\begin{aligned} &H_1-H_2-144\,A(p_1v_1-p_2v_2)\\ &=1054-1169-.1852(15\times 23.62-72\times 5.905)\\ &=-115-13\\ &=-128 \text{ B. t. u.} \end{aligned}$$

or the work done on the steam is 128 B. t. u.

Work done in the Rankine Ideal Cycle

In the Rankine cycle, steam is admitted at a constant pressure, expands adiabatically to the back pressure and is exhausted against a constant back pressure. The engine is supposed to have no clearance. It is an ideal steam-engine cycle, with no internal friction, no heat losses and no free or imperfectly resisted expansion. In such a cycle all the energy that is taken from the steam must be converted into work. The work done per lb. of steam is consequently H_1-H_2. As the only expansion that takes place is adiabatic, the steam that is leaving has the same entropy as the entering steam.

To find the work done by unit mass of steam, in a Rankine cycle admitting steam of known quality and pressure, and expanding to a known back pressure, locate the

point representing the quality and pressure of the admission steam, and measure the vertical distance from this point to the known back pressure line. This distance represents the work done in B. t. u.

Example 12. Steam initially at 150 lbs. pressure, superheated 150° F., goes through a Rankine cycle with a back pressure of 2 lbs. per sq. in. How much work is done by unit mass of steam?

The total heat of steam at 150 lbs. pressure, superheated 150° F. (Diagram I), is 1275 B. t. u. Steam of the same entropy at 2 lbs. abs. pressure has a total heat of 964 B. t. u. The work of the Rankine cycle is

$$1275-964=311 \text{ B. t. u.}$$

The Flow of Steam

In a steam engine the resistance to expansion is offered by the piston, and the useful work is done on the piston; in a steam nozzle the resistance to expansion is offered by the steam which is ahead, and consequently the work is done on the steam, and results in giving it kinetic energy.

If steam is admitted to a properly designed, non-conducting nozzle without internal friction, it will expand adiabatically. Since there is no heat loss, and no external work done, all the energy that is taken from the steam must be converted into kinetic energy. The kinetic energy of the escaping steam is consequently H_1-H_2. The velocity corresponding to this kinetic energy of unit mass of steam can be read directly from the scale to the left of Diagram I. It is evident that the kinetic energy of the escaping steam is equal to the work that would have been done by the steam in a Rankine cycle with the same back pressure.

To find the velocity with which steam escapes from a properly designed frictionless nozzle, measure with a pair of compasses the change in the total heat of the steam during adiabatic expansion and transfer this measurement to the velocity scale.

Example 13. Steam at 100 lbs. pressure, superheated 60° F., expands in a nozzle to a pressure of 2 lbs. per sq. in. What is its final velocity?

The change in the total heat is 1219−954=266 B. t. u. This is seen by the scale on Diagram I to correspond to a velocity of 3650 ft. per second.

Example 14. A four-stage impulse turbine supplied with steam as in example 13 and with expansion to the same pressure, is designed for equal velocity of steam in each of the stages. What is that velocity?

The kinetic energy of the steam in each stage is $\frac{266}{4}=66.5$ B. t. u. This corresponds to a velocity of 1825 ft. per second.

Designing a Nozzle

The design of a steam nozzle for a desired weight flow is determined by the throat (smallest cross section) of the nozzle. The pressure at the throat will be about .58 of the initial pressure whenever the ratio of the final pressure to the initial pressure is less than that quantity; for ratios greater than .58 the throat pressure is the same as the final pressure. To determine the throat area, find the velocity of the steam at the throat from Diagram I and its specific volume from Diagram II. The specific volume multiplied by the desired weight flow in lbs. per second is the volume flowing per second past the throat. This volume divided by the velocity at the throat is equal to the area of the throat, in square feet.

Example 15. 50 lbs. of steam at 160 lbs. pressure, superheated 100° F., flow per minute through a nozzle into the atmosphere (15 lbs. per sq. in.). What is the smallest cross section of the nozzle?

The entropy of the steam is 1.629 and its total heat 1251 B. t. u. At the throat the pressure is approximately $160\times.58=92.8$ lbs. per sq. in.; the total heat is 1202 B. t. u., and the specific volume is 4.98. The kinetic energy at the throat is $1251-1202=49$ B. t. u., which corresponds to a velocity of 1575 ft. per second. The volume flowing per second past the throat is $\frac{50}{60}\times 4.98=4.15$ cu. ft. The throat area is consequently $\frac{4.15}{1575}\times 144=.380$ sq. ins.

Throttling

If steam expands through a small orifice (or a porous plug) without the addition or abstraction of heat, and is brought finally to its initial velocity, its total heat will be unchanged. This must be the case because none of the heat is converted into external work or kinetic energy and no heat is added or abstracted, so that $H_1-H_2=0$. The process is called throttling, and occurs when steam goes through a reducing valve and also in the throttling calorimeter. Horizontal lines on Diagrams I and II are lines of constant total heat and consequently show the changes in the condition of steam which result from throttling.

Example 16. Steam at 200 lbs. pressure, quality .99, passes through a reducing valve. At what pressure must the valve be set in order to discharge dry and saturated steam?

Inspection of Diagram I or II shows that dry and saturated steam at 119 lbs. has the same total heat as steam at 200 lbs. and quality .99.

Example 17. Steam in a throttling calorimeter has a pressure of 17 lbs. per sq. in. and a temperature of 265° F. The initial pressure of the steam was 100 lbs. per sq. in. What was its initial quality?

Saturated steam at 17 lbs. has a temperature of 219° F.; the superheat in the calorimeter is consequently $265-219=46°$ F. The initial quality of the steam is seen by inspection to be .987.

Hirn's Analysis

In making Hirn's analysis of the performance of a steam engine it is necessary to find (from the measured pressure, volume, and weight of steam acting) the internal energy of the steam in the cylinder at admission, cut off, release, and compression. These quantities are readily found by the method already outlined.

Temperature-Entropy Diagram

In redrawing an indicator (pressure-volume) diagram on the temperature-entropy plane, the assumption is made that the whole of the working substance remains in the cylinder throughout the cycle, and that heat is added to and abstracted from it while it is in the cylinder. That is, the boiler, cylinder, and condenser operations are all assumed to take place in the cylinder. It is most convenient, moreover, to draw the diagram for unit mass of steam, which is readily done after determining the proper scale of volumes for the indicator diagram. The process then becomes extremely simple: the temperature and entropy corresponding to a series of points on the indicator diagram are found as in example 4 and are plotted. It should be noted, however, that the diagrams do not give information for qualities below about .7. Consequently some of the points on the temperature-entropy diagram must be calculated.

Other Problems

Many special problems of less common occurrence than the foregoing can be easily solved by the use of the diagrams. For example, suppose it is proposed to spray into a gas-engine cylinder a certain weight of water at a certain instant, and it is desired to know what will be the resulting pressure and temperature in the cylinder. The partial pressure, temperature and total heat of the steam formed will be represented by the coördinates of some point on a definite constant specific volume line on Diagram II; the exact position of the point on the line can easily be determined from the conditions of the problem by trial and interpolation.

PART III

DISCUSSION OF SOURCES

THE computation of a steam table requires as its foundation experimental data of several different kinds. The most important are:

1. An evaluation of the absolute thermodynamic scale;
2. Data on the variation of the specific heat of water with temperature;
3. Data on the mechanical equivalent of heat;
4. Data on the pressure-temperature relation for saturated steam;
5. Data on the specific heat of superheated steam;
6. Data on the specific volume of superheated steam;
7. Data on the total heat of saturated steam.

Each of these subjects will be discussed in a separate section. Besides them one needs:

A comparison of the fundamental units of length and of weight in the English and metric systems;

Data on the density of water at various temperatures;

A value for the density of mercury at the temperature of melting ice.

In each of these last three cases there are trustworthy values so generally accepted as to need no discussion.

§ 1. Absolute Temperature

An evaluation of the absolute thermodynamic scale is necessary because of the use which must be made of absolute temperatures in the computation of entropies. Two distinct problems are involved. The first is the determination of the absolute temperature of melting ice, that is, the location of the absolute zero; and the second is the determination, degree by degree, of the difference between the absolute scale and that of the nitrogen-in-glass thermometer which is the usual standard in scientific work. For the present purpose the second of these problems need not be considered, for the variation of the nitrogen thermometer from the absolute scale is nowhere greater than a twentieth of a degree Fahrenheit between 0° and 400°; above 400° even considerably larger errors in the temperature scale would be within the limit of error of the rest of the experimental data.

The determination of the absolute zero has recently been most satisfactorily accomplished. Three papers may be mentioned, which will themselves give references to many more, namely those of Berthelot,[1] Buckingham,[2] and Rose-Innes.[3] Berthelot worked by two very different methods, the first based on the fact that as the pressure

[1] Trav. et Mém. Bur. Int., vol. 13 (1903).
[2] Bul. of the Bur. of Stan., vol. 3 (1907), pp. 237–293 (Reprint No. 57).
[3] Phil. Mag. (6), vol. 15 (1908), pp. 301–316.

in a gas thermometer approaches zero, the gas becomes more and more perfect, and the second based on the Joule-Thomson effect. Buckingham worked only from the Joule-Thomson effect. Rose-Innes also used the Joule-Thomson observations, but supplemented them as far as possible by much more accurate recent data on coefficients of expansion. The values which these investigators give for the temperature of the ice-point are: —

Author	Year	Method	Gases	Final Value for Ice-point
Berthelot	1903	Extrapolation to p=0	H_2 and N_2	491.54° F.
"	1903	Joule-Thomson effect	H_2, N_2, CO_2 and air.	491.63
Buckingham	1907	" " "	" " " " " "	491.71
Rose-Innes	1908	J.-T. effect and other data	H_2 and N_2	491.64

Of these values the last is probably the best. Incidentally, it agrees almost exactly with the mean of the other three. Since the temperature of melting ice on the ordinary Fahrenheit scale is 32°, the value that must be added to temperatures on the ordinary scale to reduce them to absolute temperatures is

$$491°.64 - 32°.00 = 459°.64.$$

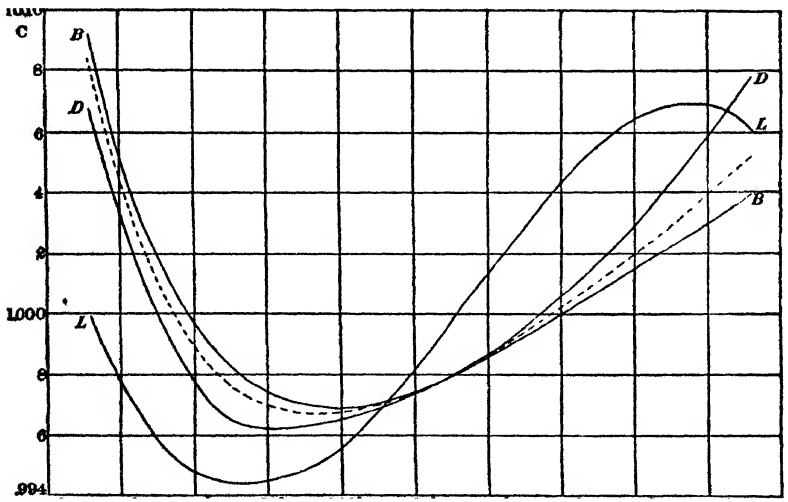

Fig. 1. — The specific heat of water between the freezing and boiling points according to Barnes (B), Dieterici (D) and Lüdin (L). The dotted curve is $(2B + D)/3$.

§2. The Variation of the Specific Heat of Water with Temperature

The only sets of experiments available over the whole range from 32° to 212° F. are those of Lüdin,[1] Barnes,[2] and Dieterici.[3] Since this part of the discussion is concerned only with the shape of the curve of variation of the specific heat, c, with tem-

[1] Inaug. Diss., Zurich, 1895: recomputed, Fortsch. d. Phys. vol. 56II (1900), p. 304.
[2] Phil. Trans., vol. 199A (1902), pp. 149–263.
[3] Wied. Ann., (4) vol. 16 (1905), pp. 593–620.

perature, and not with its height, the actual values of each of these observers have been multiplied by such a constant as to make the average value of c between 32° and 212° exactly 1. This is equivalent to expressing each set of values in terms of the well-known Bunsen or mean calorie, if the temperatures are on the Centigrade scale, or in terms of a corresponding mean B.t.u., if the temperatures are on the Fahrenheit scale. The resulting curves are shown in Figure 1. Lüdin's values are generally regarded as the least trustworthy, partly because of the difficulties inherent in calorimetry by the method of mixtures, and partly because his maximum just below the boiling point is not corroborated by either of the other observers, or by Regnault, either for water or for any other liquid. Of the other two pieces of work, Dieterici's is not as convincing as the extraordinarily good work of Barnes as regards either perfection of method or consistency of results. Barnes' values have therefore been given most weight in arriving at a representative curve. Lüdin's values have been given no direct weight whatever, but the fact that his curve and Dieterici's both differ from that of Barnes in the same direction throughout encourages one to give to Dieterici's values rather more weight in comparison with Barnes' than might otherwise have seemed desirable.[1] The values finally chosen are a mean between those of Barnes and those of Dieterici, giving the former twice as much weight as the latter. The curve representing these mean values is dotted in Figure 1, and its ordinates are tabulated in the sixth column of Table 6 at the end of Part I of this book. The values there given for temperatures below the freezing point are from the work of Barnes and Cooke.[2] The values of the heat of the liquid, in Tables 1, 2 and 3, were obtained by a step by step, numerical evaluation of the integral $h = \int_{32}^{t} c\, dt$.

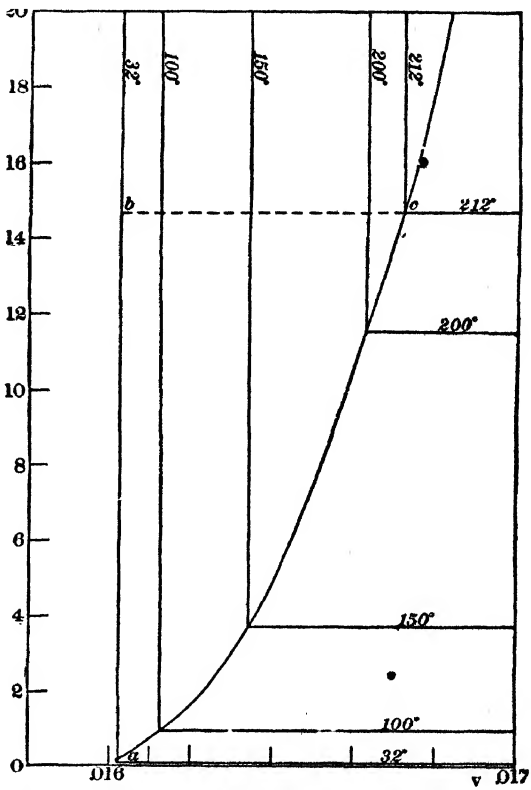

FIG. 2. — A large scale drawing of a piece out of the lower left-hand corner of the steam dome on the ordinary pv plane, illustrating the meaning of "the heat of the liquid." Abscissæ are in cu. ft.; ordinates are in lbs. per sq. in.; temperatures are on the Fahrenheit scale.

[1] See also p. 91.

[2] Phys. Rev., vol. 15 (1902), pp. 65–72.

It should be noticed that between 32° and 212° F. there are two theoretically distinct sets of numbers which could properly be given under the heading "the heat of the liquid" in a steam table, according to whether water at 32° and atmospheric pressure, or water at 32° and the pressure of its saturated vapor, is used as the zero of total heat. Figure 2 represents, drawn to scale, but much magnified, the lower left-hand corner of the steam dome on the usual pv plane. According to the first scheme, water at the point b is chosen as the zero of total heat, and the values of h which correspond to temperatures between 32° and 212° are those along the line bc. According to the second scheme, water at the point a is the zero of total heats, and the values of h given are those along the water-line ac. Since the internal energy, e, of water at b is very nearly the same as that of water at a, practically all of the difference between the h at b and the h at a comes in the second term of the usual equation

$$h = e + 144\, Apv.$$

Graphically, this difference is the equivalent in heat units of the area of the rectangle between the vertical line ab of Figure 2 and the p axis; and in general the difference between the two possible values of h at any temperature is the area of a similar rectangle to the left of some vertical line between ac and bc.

A comparison of the two possible sets of h values with each other, and with the values of e along the same two lines, is given in the following table. The "mean B. t. u.," which is the heat unit employed, is, by definition, the one hundred and eightieth part of the change in total heat along bc.

Description	Value at 32°	Value at 212°	Range
e along ac	0.00000	179.99813	179.99813
e along bc	0.00002	179.99813	179.99811
h along ac	0.00026	180.04362	180.04336
h along bc	0.04362	180.04362	180.00000

The distinction between the two possible sets of h values is of practical importance only in accurate calorimetry by the method of mixtures, and for that purpose h values along bc are preferable. They are given to two decimal places in Table 1 to facilitate this use of them. As a matter of convenience they have been reduced to b as the zero state, and satisfy the unusual but equally permissible equation of definition

$$h = e + 144\, Apv - 0.04362$$

At high temperatures only values on the second scheme are possible, so that, in careful thinking, different interpretations of the phrase "heat of the liquid" are necessary in different temperature ranges.

Above 212° there are available only two investigations, Dieterici's and Regnault's.[1] The latter's observations were by the method of mixtures, the mean temperature of the cold water in the calorimeter varying from 55° to 70° F. Since the specific heat of

[1] Mém. de l'Inst. de France, vol. 21 (1847), pp. 729–748.

water changes rapidly with the temperature in that range, it has seemed worth while to recompute Regnault's results on the basis of the curve just obtained for c below 212°. Figure 3 shows on a large scale the difference between the recomputed heat of the liquid from Regnault's data and that on the assumption that c is constant and equal to one. In other words, ordinates in Figure 3 are the increments that must be added to the mere temperature difference $(t-212)$ to give, for any temperature t, the heat of the liquid above that at 212°. The curve R, representing Regnault's observations, does not approach zero at 212° as it should, which means that Regnault's experiments are inherently inconsistent with the c curve adopted above for the range from 32° to 212°. Regnault's experiments require the curve to be lower at room tempera-

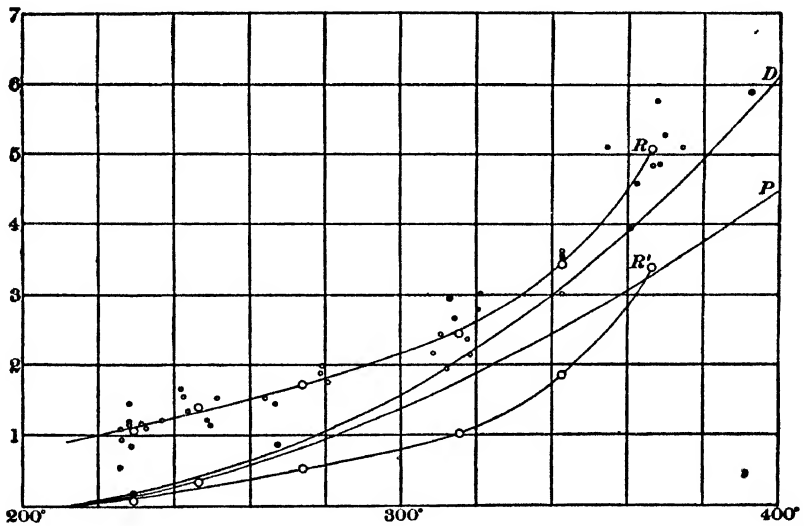

FIG. 3. — The heat of the liquid (h) above the boiling point. Abscissæ are temperatures on the Fahrenheit scale. Ordinates are Δh in B. t. u. where Δh is what must be added to $(t-32)$ to give h. The recomputed results of Regnault's forty experiments are represented by small circles, and their means, in six groups, by large circles (curve R); curve R' is curve R scaled down to pass through 0 at $t=212°$. Curve P is Peabody's recomputation of Regnault's curve, also scaled down to pass through 0 at $t=212°$. Curve D represents Dieterici's formula and is the one used in this book. The black dots are five of Dieterici's twenty experimental means. The middle one of the five shown is the most inconsistent of the whole twenty. Dieterici's formula represents fairly well his other values at temperatures above 400° F.

tures and consequently higher near the boiling point than is the mean curve chosen above — that is, they require a curve still more like Dieterici's and still less like Barnes' than that chosen, thus justifying the decision that Dieterici's results should have a weight of at least one in three. Perhaps they should have had even more weight, but the work of Barnes has always been regarded as of such extraordinary excellence that this has not seemed best at the present time.

If Regnault's values are multiplied by such a constant factor as will make them approach zero at 212°, his curve lies below either Dieterici's or that marked P in Figure 3,

which represents Peabody's version of Regnault's experiments,[1] but turns sharply up across Peabody's curve toward Dieterici's near 400° F. The arbitrary nature of this scaling-down process is, however, an argument against the acceptance of the resulting curve.

Dieterici's curve is also open to objection in that his observed points do not lie as near it as might be wished, especially in the temperature range of Figure 3. The position of his curve is fixed largely by the points at higher temperatures.

The whole subject is still, therefore, in an unsatisfactory condition above 212°. Fortunately it makes very little difference in the properties of saturated steam which values are used for the heat of the liquid. For instance, the whole of the outstanding discrepancy at 400° would make about a thirtieth of one per cent difference in the entropy of saturated steam at that temperature. The values of Dieterici above 212° have, therefore, been chosen because of the great range covered by his experiments, even though this involves a slight discontinuity in $dh/dt=c$ at 212°. His formula for the mean specific heat from 32° F. to t° F. may be written

$$c_m=0.9983-0.000\,028\,8(t-32)+0.000\,002\,133(t-32)^2 \text{ mean B. t. u.}$$

Strictly speaking, this formula leads to values, not of h, but of e, but the difference is, in general, smaller than the outstanding uncertainties in either, being 0.046 B.t.u. at 212°, about 0.2 B.t.u. at 300°, and only 0.85 B.t.u. at 400°. Neglecting it, as has been done in these tables at temperatures below 450°, simply means using as standard a compromise (namely curve D on Figure 3) between the true Dieterici curve, which would lie somewhat higher than curve D, and Regnault's results as represented by either curve R or curve P. Above 450°, where the difference between e and h gets big, it has been allowed for.

§3. The Mechanical Equivalent of Heat

The values of the specific heat of water discussed in the last section are in thermal units; some one of them must now be determined in mechanical units. For this purpose there are available the experiments of Rowland,[2] and of Reynolds and Moorby,[3] by whom mechanical work was transformed directly into heat, and the experiments of Griffiths,[4] of Schuster and Gannon,[5] and of Barnes,[6] by whom electrical energy was changed into heat. These investigations have recently been discussed by Smith,[7] who accepts as most trustworthy the mean of the values of Reynolds and Moorby and of Barnes, namely

$$1 \text{ mean calorie} = 4.1834 \times 10^7 \text{ ergs.}$$

[1] Reduced to mean B.t.u. by subtracting a seventh of one per cent.

[4] Phil. Trans., vol. 184A (1893), pp. 361–504.
[5] Phil. Trans., vol. 186A (1895), pp. 415–467.
[6] Phil. Trans., vol. 199A (1902), pp. 149–263.
[7] Monthly Weather Review, October, 1907.

To change this into English units, one needs the conversion factor[1]

$$1 \text{ kg.} = 2.204622 \text{ lbs.}$$

and a value of the gravitation constant g for which

$$g = 980.665 \text{ cms. per sec.}^2$$

has been adopted as standard by international agreement.[2] The result is

$$1 \text{ mean B. t. u.} = 777.54 \text{ standard ft. lbs.}$$

This value has been used in these tables.

§4. Pressures and Temperatures of Saturated Steam

The classical experiments on this subject were performed by Regnault[3] in the year 1847, and are even now models of accuracy. They covered the range from $-27°$ to 363° F. They have been recomputed with slightly varying results by several authors, among whom are Broch,[4] Peabody,[5] and Henning.[6] Since Regnault's time, many other investigations have been published, eleven of which are carefully discussed by Henning.[7] He uses as a standard of reference a formula of Thiesen,[8] which expresses p in mms. of mercury (at 0° C.) as a function of t in degrees Centigrade, as follows: —

$$(t+273) \log \frac{p}{760} = 5.409\,(t-100) - 0.508 \times 10^{-8}\,((365-t)^4 - 265^4).$$

The deviations, from this formula, of Regnault's observations and of those of the eleven later investigators are plotted on a large scale in Henning's paper, and a correction curve for the formula obtained graphically. The conclusions reached in this paper were the basis of the original computations for these tables. The use of Thiesen's formula is greatly facilitated by a table in Henning's paper, giving p in mms. of mercury for every degree from 0° to 200° C.

More recently, in August, 1908, Holborn and Henning have published the results of new experiments at the Reichsanstalt covering the range from 125° to 400° F. with extraordinary precision, and have proposed a new correction curve for Thiesen's

[1] See Fischer, Bul. of the Bur. of Stan., vol 1 (1904–5), p. 380.

[7] Loc. cit.; see also Risteen, The Locomotive, vol. 26 (1907), pp. 183–190, 246–254; and vol. 27 (1908), pp. 54–62.

[8] Wied. Ann., N. F., vol. 67 (1899), p. 692.

formula based on their own work down to 125° F. and on Thiesen's experiments near the freezing point. Above 212° the new curve, Henning's 1907 curve, and the curve which represents Henning's recomputation of Regnault's observations, all agree within a twentieth of a degree Fahrenheit, so that the pressure-temperature relation may be regarded as satisfactorily known. Below 212° the new saturation temperatures run slightly higher than those of the 1907 paper, the greatest change being 0.12° F. at a pressure of 1 lb. Those parts of the tables which are affected by the change have been recomputed and corrected in page proof.

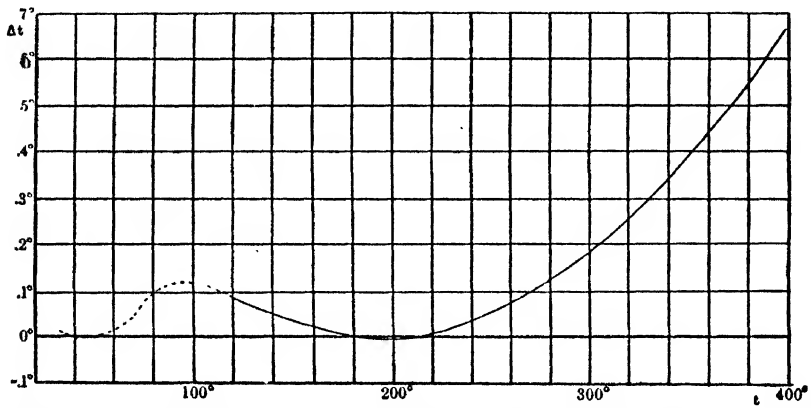

FIG. 4. — Correction curve for Thiesen's formula, according to Holborn and Henning (1908). Abscissæ are temperatures; ordinates are $\Delta t = t_{obs.} - t_{calc.}$

To make Thiesen's formula available in English units, one needs the density of mercury at 0° C. According to Thiesen and Scheel [1]

1 cu. cm. of Hg. at 0° C. weighs 13.59545 grs.

In the computation of the condenser vacuum column in Table 1, giving p in inches of mercury, one needs also

1 meter = 39.37 U. S. standard inches.[2]

Thiesen's formula, expressed in English units, is

$$(t+459.6)\log\frac{p}{14.70} = 5.409\,(t-212) - 8.71\times 10^{-10}\,((689-t)^4 - 477^4),$$

where p is in lbs. per sq. in. and t is in ordinary Fahrenheit degrees. The correction curve of the 1908 paper of Holborn and Henning is plotted in English units in Figure 4, in which ordinates are Δt = observed temperature minus the t in Thiesen's

[1] Z. S. f. Instrkde., vol. 18 (1898), p. 138.

[2] This is the legal definition of the U. S. standard inch. See Fischer, Bul. of the Bur. of Stan. vol. 1 (1904–5), pp. 365–381, particularly p. 380.

formula. To use this curve to get the pressure corresponding to a given temperature $t°$, one first *subtracts* from that t the Δt given by the curve, and then substitutes the remainder in Thiesen's formula.

At the very high temperatures considered at the end of Table 1, three researches are available, namely those of Battelli,[1] of Cailletet and Colardeau,[2] and of Knipp.[3] The results of these observers are not in good agreement, as the following table shows. The values of Cailletet and Colardeau were used in the preparation of Table 1.*

Temp. Fahr.	Pressure in Atmospheres According to Battelli	C and C.	Knipp
400°	16.8	16.8	
500°	48.6	46.6	47.1
600°	109.7	107.1	112.5
680°	186.7	189.0	207.7

§5. The Specific Heat of Superheated Steam

Here, as before, the classical research is that of Regnault,[4] published in the year 1862. Contrary to an assumption sometimes seen in the literature, his work does not even seem to prove that the specific heat at constant pressure (C_p) of superheated steam is independent of either the pressure or the temperature, for he made only four series of experiments, and these were all at atmospheric pressure and covered nearly the same temperature range. He worked by the method of mixtures, injecting a known weight, first of slightly superheated steam, and then of highly superheated steam, into a calorimeter filled with water at room temperature. His computations are in error because, instead of weighing the cold water in the calorimeter, he measured it volumetrically in a suitable cast-iron tank. His justification of this was that although, by reason of the thermal expansion of the water as compared with that of the tank, there was less water by weight at room temperature than at 0° C., which was his standard temperature, nevertheless the fact (which he thought to be true at low as well as at high temperatures) that the specific heat of water increased with the temperature, made the water in the calorimeter more effective thermally, gram for gram, and just about made up for neglecting its change of density. But we now know that at room temperatures the specific heat of water decreases with rising temperature. His data have, therefore, been recomputed, using his own value for the expansion coefficient of his sheet-iron tanks and modern data for the density and specific heat of water. This slightly reduces each of his four values of C_p to the following figures: —

[1] Mem. d. R. Acc. d. Sc., Turin (2), vol. 43 (1892), pp. 63–98; see also Ann. de Chem. et de Phys. (6), vol. 26 (1892), pp. 410–425; and especially Risteen, The Locomotive, vol. 26 (October, 1906), pp. 116–126, and vol. 26 (July, 1907), pp. 213–219.

[3] Phys. Rev., vol. 11 (1900), pp. 141–144.

[4] Mém. de l'Inst. de France, vol. 26 (1862), pp. 167–178.

* See page 4.

	Temp. Range ($C°$)	R's Value of C_p	New Value of C_p
Series 1.	127.7–231.1	(0.46881)[1]	(0.4655)
Series 2.	137.7–225.9	0.48111	0.4769
Series 3.	124.3–210.4	0.48080	0.4736
Series 4.	122.8–216.0	0.47963	0.4780
	Mean of last three	0.48051	0.4762

It will be seen presently that the new figures agree better with modern work than do the older ones.

It is only within a few years that reliable determinations of C_p at other pressures than 1 atmosphere have been made. The best of these are probably those of Knoblauch and Jakob,[2] which were carried out with great care by the electrical method. Steam from a boiler was superheated in an apparatus consisting of a long pipe some inches in diameter filled with a dense grid of resistance wire, wound on insulating frames. The energy necessary for superheating was introduced electrically in the first sections of this pipe and the rest of the resistance wire served to mix the steam and bring it into a homogeneous state. It then passed into a calorimeter where a small amount of additional energy was introduced electrically, careful measurements being made of the temperatures of the steam when entering and leaving this calorimeter. The losses due to radiation and conduction were determined by separate experiments. The C_p of the steam in the calorimeter could then be easily computed. The results of these experiments have been used as the basis for the computation of these tables.

They have, however, been modified in two respects. In the first place, the curve giving the C_p of steam at atmospheric pressure has been lowered in the high temperature region, so as to agree better with the values obtained by Holborn and Henning[3] at very high temperatures. Their work, like Regnault's, was only at atmospheric pressure, but they reached temperatures as high as 2450° F., and others by different methods have gone even higher. All these results agree in giving smaller values of C_p than an extrapolation of Knoblauch and Jakob's atmospheric curve would indicate. It has therefore been lowered so as to join continuously with the curve of Holborn and Henning.[4] The high

[1] "... les résultats de la première série, qui m'inspirent moins de confiance que les autres. ..." Regnault, p. 178.

[2] Forscharb., Berlin, Hefte 35 and 36 (1906), pp. 109–152.

[3] Wied, Ann., (4) vol. 18 (1905), pp. 730–756; and (4) vol. 23 (1907), pp. 809–845.

[4] (Note added, June, 1912). The propriety of this change in the original curve of Knoblauch and Jakob has been justified since the first copies of this book were printed by the results of a new investigation by Knoblauch and Mollier (Z. V. D. I., 1911, pp. 665–674) covering the same range of pressure as their earlier investigation, but extending to over 1000° F. This work shows that their former C_p curve for 1 atmosphere rose too sharply near 650° F. and that the true curve lies nearly as it was drawn in figure 5. Their results run a little higher, however, than Holborn and Henning's, and it is therefore possible that the values of C_p used in this book for the highest temperatures are a little too low. No error of commercial importance is involved.

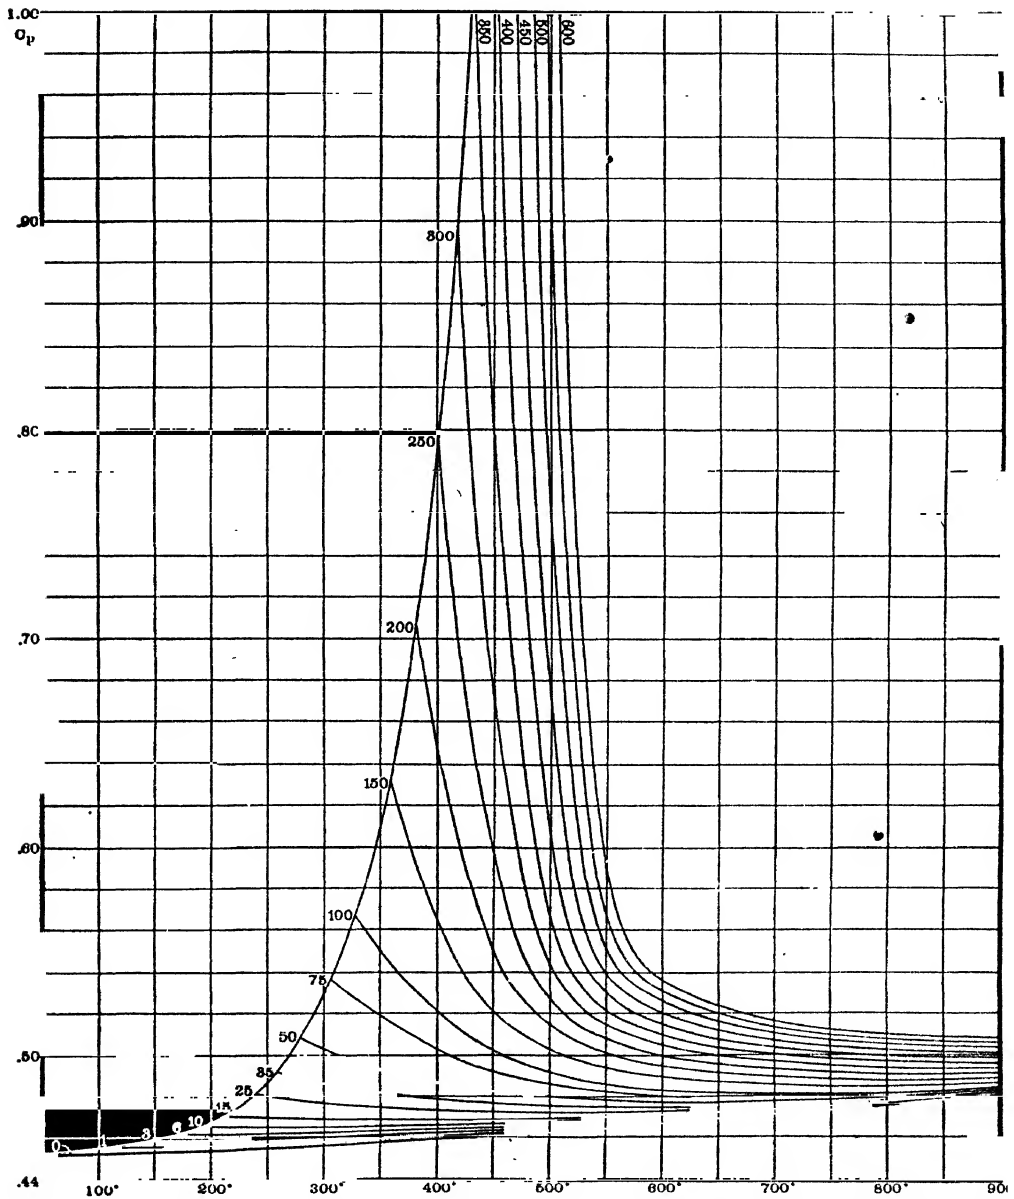

FIG. 5. — The specific heat at constant pressure of superheated steam as used in this book, extrapolated from Knoblauch's data. The saturation line is drawn according to his formula, and the curves at moderate pressures and superheats follow his curves as nearly as possible. The curves at very low pressures close to saturation are higher than Knoblauch's curves because of thermodynamic evidence, and because of Regnault's results at atmospheric pressure. The 15 lb. curve at high superheats follows Holborn and Henning's curve. The other curves are spaced at very high superheats in accordance with information derived from the Joule-Thomson effect.

temperature ends of the other curves, for pressure higher than 15 lbs., have then been spaced in accordance with information which can be derived from a study of the Joule-Thomson effect in superheated steam and in other vapors.[1]

The second modification of Knoblauch's curves is at the low temperature end of the 15 lb. curve and those near it. These run lower than even the recomputed results of Regnault's observations, to which considerable importance may well be attached in the present unsettled state of the subject. There are also certain theoretical considerations based on the thermodynamics of the Joule-Thomson effect which seem to set 0.45 as a lower limit to the lower end of the saturation line on the C_p diagram, a value also somewhat higher than Knoblauch's. For these reasons, the curves below 100 lbs. have all been slightly raised on the C_p diagram. The difference at 15 lbs. is only 0.007 B. t. u.

The finally accepted values of C_p, which were used in the preparation of these tables, are plotted in Figure 5. They have received additional confirmation from the fact that all of seven different kinds of large scale steam diagrams which have been plotted in the course of this work, and particularly the total heat-temperature diagram on which the lines of constant pressure seem to be very sensitive to inconsistencies in the assumed values of C_p, ran more smoothly with these values of C_p than with certain other suggested values which were first tried.

§6. The Specific Volume of Superheated Steam

Of the various sets of values of the specific volume of superheated steam at different pressures and temperatures, that of Knoblauch, Linde and Klebe [2] seems to be the best, and has been used in this work.[3] Linde's characteristic equation,[4] expressing v as a function of p and t, may be written

$$pv = 0.5962\ T - p\,(1 + 0.0014\ p)\left(\frac{150{,}300{,}000}{T^3} - 0.0833\right),$$

where p is in lbs. per sq. in., v is in cu. ft., and $T = t + 459.6$ is the absolute temperature on the Fahrenheit scale.

§7. The Total Heat of Saturated Steam

It is in their values for the total heat of saturated steam that these tables differ most essentially from all that have preceded them. It has been the custom for makers of steam tables to use Regnault's classic formula,[5] now sixty-one years old, which gives as the total heat of saturated steam

$$H = 1091.7 + 0.305\ (t - 32).$$

[1] Davis, Proc. Am. Acad., vol. 44 (1909).
[2] Forscharb., Berlin, Heft 21 (1905), pp. 33–55.
[3] But see p. 103.
[4] Forscharb., Berlin, Heft 21 (1905), pp. 64–69.
[5] Mém. de l'Inst. de France, vol. 21 (1847), pp. 635–728.

It has for some time been known that this formula was considerably in error, especially at low temperatures, and it is worth noticing that of the eight other vapors studied by Regnault, five gave curves of the second degree, concave downward, for H as a function of t.

Since Regnault's time, measurements of great value, either of the total heat itself, or of the heat of vaporization, which amounts to the same thing, have been made at various temperatures between 32° and 212° F. by Dieterici, Smith, Griffiths, Henning and Joly, all of which have been admirably discussed by Smith in the paper previously referred to.[1] Their values as recomputed by him are given in the following table:—

Observer	Temperature Degrees Fahr.	Total Heat B. t. u.

* These four values were considered by the experimenters less reliable than their other results.

These values have been plotted on a large scale and a graph drawn representing satisfactorily practically all of them, from which the values used in this book at temperatures below 212° were then read off. Regnault's formula, and those tables which are based on it, are right at 170° F., but are too high by 18 B. t. u. at 32° F.

Above 212°, Regnault's values may be replaced by a second degree equation recently proposed by one of the present authors [3] on the basis of a recomputation of the throttling experiments of Grindley, Griessmann and Peake, with the help of the C_p measurements of Knoblauch and Jakob, already referred to. The method used is illustrated by Figure 6, the left-hand half of which represents a throttling curve of the

[2] See also Wied. Ann., (4) vol. 16 (1905), pp. 593–620.
[3] Davis, Proc. Am. Soc. of Mech. Engs., vol. 30 (November, 1908), pp. 1419–1432.

sort published in the papers mentioned. Supposedly dry and saturated steam at the pressure and temperature corresponding to the point A is first throttled to a lower pressure and temperature corresponding to the point B; then in a later experiment in the same run, it is throttled from exactly the same initial condition A to the condition C; then to D and so on. The well-known law of throttling is that the total heat in the condition B, or C, or D, is equal to that in the initial condition A.

The point B represents superheated steam at the pressure p_B; the point B' represents saturated steam at the same pressure; the amount of superheat at B is the known temperature there minus the temperature at B', which can be taken from a steam table. Also, by definition, the total heat at B equals that of saturated steam at the same pressure (point B') plus the amount of heat required to superheat it at constant pressure from B' to B. This is the integral of C_p from B' to B, or simply the mean C_p from saturation multiplied by the known superheat. If C_p is known, this integral or increment in the total heat between B' and B is easily evaluated.

The value obtained is not only the difference between the total heat of saturated steam at B' and that of superheated steam at B; it is also the difference between the total heat of saturated steam at B' and that of saturated steam at A; that is, between the two corresponding ordinates of a curve giving the total heat of saturated steam as a function of the temperature. To draw a piece of this curve, one chooses arbitrarily some horizontal line such as xy in Figure 6, and lays off below it, at the proper temperatures, the distances bb', cc', dd', etc., which represent on the desired H-scale the integrals or total heat differences between B' and B, C' and C, D' and D, etc. The curve $ab'c'd'$ is an isolated piece of the true curve of total heat against temperature. The *relative* height of its points, that is, its shape, is accurately determined; its *absolute* height above the assumed zero of total heat, namely, water at 32° and atmospheric pressure, is not yet known.

In the paper referred to, twenty-four overlapping pieces of this sort were superposed and gave a well-defined curve. Its height was then so determined as to make it pass through the mean of the values near the boiling point of Henning and of Joly, each reduced to 212°. The resulting curve leads to the formula

$$H = 1150.3 + 0.3745(t-212) - 0.000550(t-212)^2.$$

It agrees satisfactorily, in the range from 212° to 400° F., with the values which Linde [1] computes from the volume measurements of Knoblauch, Linde and Klebe, and also with the values recently proposed by Henning [2] on the basis of an extrapolation of a formula representing his results below 212°.[3] It is certainly much better than Regnault's formula, and is probably within a tenth of one percent of the truth throughout the range considered. If it be even that much in error, it is probably because it runs too low at the high temperatures. It has been used for the range above 212° in these

tables. It shows that Regnault's formula, and those tables which are based on it, are too high by 6 B.t.u. at 175°, are right at 280°, and are too low at higher temperatures, the error increasing as the square of $(t-175)$.

It has been pointed out [1] that the "total heat of saturated steam" obtained in this way is, rigorously, slightly different from that measured by Regnault. The new H is defined by the equation already mentioned in section 2,

$$H=E+144\ Apv-0.04 \quad \text{mean B.t.u.},$$

where E is the internal energy of the saturated steam and v is its volume. Regnault's H was smaller by the amount of the feed-pump work required to force water *at the*

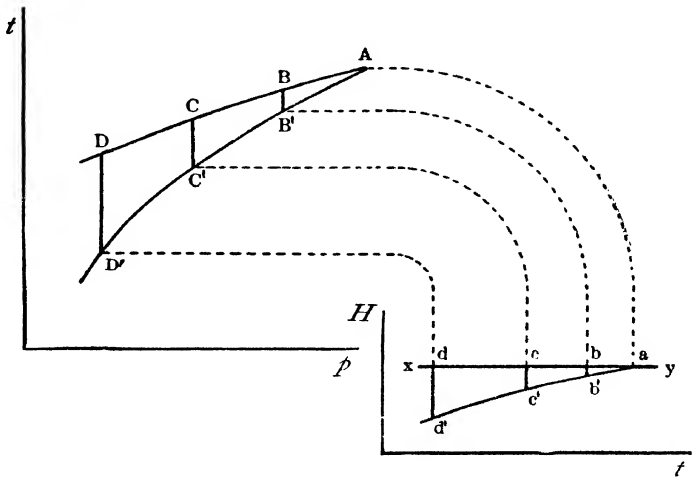

FIG. 6. — Showing how the total heat curve *ab'c'd'* is obtained from a throttling curve, *ABCD*.

temperature of the room into an enclosure against the pressure of the high temperature steam under investigation. Regnault's H gives accurately the heat required to turn feed water under pressure at *his* room temperature into steam in the delivery pipe, but is not as useful for other purposes as the H defined above; furthermore, it is not an accurately definable concept, depending as it does not only on the temperature of the saturated steam itself, but also on the temperature of the feed water. It is desirable, therefore, to displace it in both scientific and technical thinking by an H defined as above. This is the usual practice abroad.

From H it is easy to compute L, the latent heat of evaporation, by subtracting h, the heat of the liquid.

$$L=H-h.$$

In many places in Tables 1 and 2, the values given for H, h and L will fail to satisfy this equation by one unit in the last place. This is because they were made to satisfy it when carried to an extra decimal place, the discrepancy coming in when the extra place was dropped.

[1] Heck, Jour. of the Am. Soc. of Mech. Engs., vol. 31 (1909), p. 301.

At the end of Table 1, an attempt has been made to obtain by an extrapolation at least a qualitative idea of the variation of L and H with temperature in the range between 400° and the critical point. For this purpose L is easier to work with than H, because its behavior at the critical temperature itself is definitely known, at least if the usually accepted ideas about the critical point are assumed to be correct. These demand that at that point $L=0$ and $dL/dt=$minus infinity. As to H, it can be proved on the same hypotheses that $dH/dt=$minus infinity, but no information can be obtained as to the value of H itself. The two assumed facts about L led Thiesen [1] to suggest as an empirical formula

$$L=C\ (t_k-t)^n,$$

where t_k is the critical temperature of water and C and n are constants to be determined experimentally. For n Thiesen used $\frac{1}{3}$, and Henning was led by his experiments below 212° F. to $n=0.31249$. A redetermination of this constant with the help of the new values above 212°, just described, leads to $n=0.3150$. If 138.81 B. t. u. be used for C, Thiesen's formula represents not only the seventeen values below 212° already tabulated, but also the eighteen mean values from which the new equation above 212° was obtained, with an average error of only one sixteenth of one per cent. It has, therefore, been used as the basis of an extrapolation to the critical point. The resulting values, which are given at the end of Table 1, are, of course, only qualitatively reliable. (See also page 4.)

§8. The Specific Volume of Saturated Steam

The adoption of a set of values for the total heat of saturated steam makes possible two useful computations. The first of these has already been mentioned on page 96, and gives C_p close to the saturation line by means of the formula [2]

$$C_p=\frac{dH}{dt}-\frac{L}{T}+\frac{L}{u}\left(\frac{dv}{dt}\right)_p.$$

The results of such a computation have been published elsewhere,[3] and seem to justify the decision that Knoblauch's values of C_p are preferable to Thomas'.

Of much greater importance is the possibility of computing u, the change of volume during vaporization, by means of Clapyron's equation, where p is in lbs. per sq. in.

$$u=\frac{L}{144AT}\ \frac{1}{(dp/dt)_{\text{sat.}}}.$$

The necessary values of dp/dt were obtained by the method suggested in Henning's 1907 paper, the derivative of Thiesen's formula for $p=f(t)$ being computed arithmetically, and an unimportant correction factor being obtained graphically from the

[1] Verh. Phys. Ges. zu Berlin, vol. 16 (1897), pp. 80–82.

[2] For derivation, see, for example, Griessmann, Forscharb., Berlin, Heft 13 (1904), p. 8.

[3] Davis, Proc. Am. Soc. of Mech. Engs., vol. 30 (November, 1908), pp. 1429–1431; and vol. 31 (February, 1909), pp. 309–310.

correction curve representing Henning's new results. To the values of u thus obtained must be added the specific volume, v', of water [1] to give the specific volume, v, of saturated steam.

The results differ considerably from those obtainable from Regnault's total heats (see curve R of Figure 7). They agree remarkably well with the actual measurements of Knoblauch, Linde and Klebe between 212° and 360° F. (see curve K of Figure 7), the discrepancy only once reaching 0.2%, which is the limit of error assigned by the experimenters to their work.

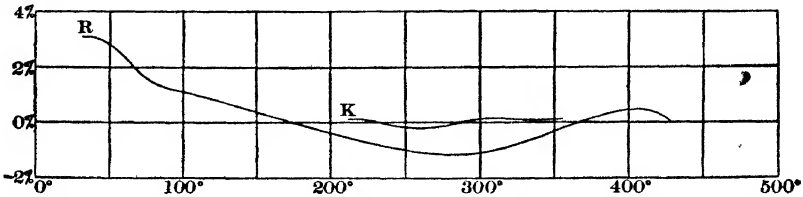

FIG. 7. — This figure shows the percentage deviation from the new values of the specific volume of saturated steam, first, of Regnault's values as given, for example, in the 1907 edition of Peabody's tables (curve R), and second of Knoblauch's experimental values (curve K). The irregularity below 100° is caused by the curious curvature in the lower part of the curve of Figure 4.

In Table 3 the values of v at saturation are the Clapyron values just described, while above 50° superheat, Linde's characteristic equation has been used. Between saturation and 50° superheat the values are such as to give a gradual transition. At high superheats Linde's equation is wholly an extrapolation, and the values of v should not be accepted with much confidence, the limit of error being uncertain.

§9. The Specific Volume of Steam at Very High Temperatures

The extrapolated values of the latent heat of vaporization discussed in section 6, together with the data on vapor tensions at very high temperatures discussed in section 4, make possible at least a qualitatively accurate computation, by Clapyron's equation, of the change of volume during vaporization up to and including the value $u=0$ at the critical point. Furthermore, the values of the specific volume of water in Landolt and Börnstein's tables run to about 600° F., so that up to that temperature the specific volume of saturated steam can be computed by the method used at ordinary temperatures.

Above 600° another device is furnished by a law proposed in 1886 by Cailletet and Mathias,[2] called "the law of the straight diameter." According to this law, if the means of the densities of a saturated vapor and its liquid at the same pressure and temperature are plotted (as abscissæ) against the corresponding temperatures (as ordinates), the resulting curve is so nearly straight and so nearly vertical up to and including the critical point itself, that its abscissa at even a somewhat uncertain

[1] The required values of the specific volume of water, v', were taken from the 3d (1905) edition of Landolt and Börnstein's "Physikalische Tabellen."

[2] Comptes Rendus, vol. 102 (1886), pp. 1202–1207; and vol. 104 (1887), pp. 1563–1568.

critical temperature is a very good determination of the critical density. This law has been experimentally verified for many different substances by Mathias, Young, Guye, Tsuruta and others.[1] It is found that the diameter is usually not exactly straight, but that a second degree equation

$$s = s_0 + at + bt^2$$

represents even the most exact experimental data with satisfactory accuracy, except in the case of the alcohols, which require an additional term in t^3. The method is now regarded as furnishing by far the best attainable value of the critical density of a substance.

The application of this law to water, which seems to be new, is illustrated in Figure 8. This figure shows not only the diameter itself (large circles), but also the vapor and liquid densities (small circles) of which its points are the means. The steam dome on this figure is analogous to that on the ordinary pv plane except that right and left are interchanged, and that the shape of the top is much flattened because of the crowding of a large pressure range into a small temperature range. The curvature in the diameter is noticeable but regular, and its points can be represented well within the limit of error of the data by the formula

$$s = 28.424 - 0.016\ 50(t-320) - 0.000\ 013\ 2(t-320)^2.$$

The substitution in this formula of the critical temperature, $t_c = 689°$ F., gives for the critical density and volume the values

$$s_c = 20.5 \text{ lbs. per cu. ft.},$$
$$v_c = 0.049 \text{ cu. ft. per lb.}^*$$

These may be compared with the only values previously reported, namely Battelli's[2] experimental value $s_c = 13.0$ lbs. per cu. ft. (point B in Figure 8), Nadejdine's[3] experimental value $s_c = 26.8$ lbs. per cu. ft. (point N in Figure 8), and Dieterici's[4] value $s_c = 15.5$ lbs. per cu. ft. (point D in Figure 8). Neither of the experimental methods of the first two observers is, in general, comparable with that of Cailletet and Mathias for the accurate determination of a critical volume, although each is admirably adapted to the determination of a critical pressure. It is probable, therefore, that the new value of the critical density is much better than either of the older experimental ones. Dieterici's value was computed on the basis of Young's law that, for "normal sub-

* These values should now (1916) be $t_c = 706.1°$ F., $s_c = 20.1$ lbs. per cu. ft., $v_c = 0.050$ cu. ft. per lb.

stances," the ratio of the actual density at the critical point to that predicted by the gas law is very nearly the same for all substances, an average value being 3.7. The discrepancy between the experimental value just found and the computed value is of the same sort as the well-established discrepancies in the case of methyl and ethyl alcohol and of acetic acid, which are regarded as indicating the existence of double

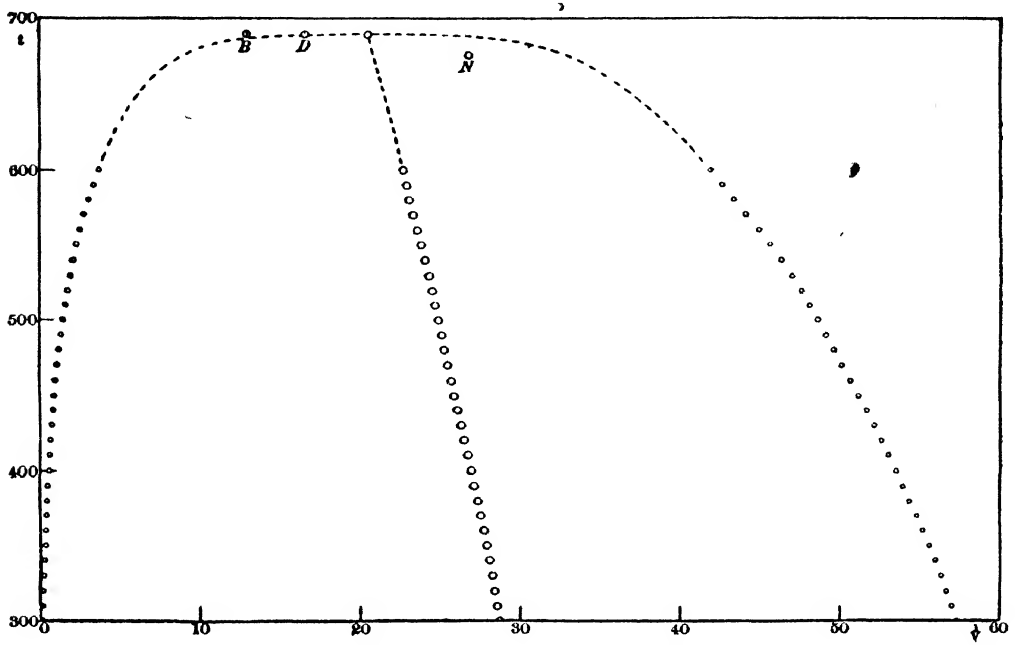

FIG. 8. — A determination by means of Cailletet and Mathias's law of the straight diameter of the critical volume of water and of the specific volumes of water and of steam at very high temperatures.

and triple molecules in those substances. A similar explanation in the case of water is very reasonable, since liquid water is known to be very highly associated at ordinary temperatures.

The equation for s, written above, gives at any temperature in the previously unknown range between 600° and 689° a value of

$$s = \frac{d_{st.} + d_{w.}}{2} = \frac{1}{2}\left(\frac{1}{v_{st.}} + \frac{1}{v_{w.}}\right).$$

Also Clapyron's equation gives a value of

$$u = v_{st.} - v_{w.}.$$

A simple algebraic manipulation of s and u gives both $v_{st.}$ and $v_{w.}$. The values at the end of Table 1 were obtained in this way. They are, of course, only qualitatively reliable because of the uncertainty in L and therefore in u.

§ 10. The Computation of the Tables

The processes by which the various values set down in the tables were obtained from these experimental data are in most cases obvious. In Tables 1 and 2, the first eight columns depend directly on the data selected. The ninth column, giving the internal energy of evaporation, comes from the formula

$$I=L-144\ Apu;$$

and the tenth column, giving the internal energy of saturated steam, from the corresponding formula

$$E=H-144\ Apv.$$

The entropy of the liquid, in column eleven, was computed by a step by step, numerical evaluation of the integral

$$n=\int_{32}^{t}\frac{c}{T}dt$$

up to 212°, and above 212° by an ordinary integration of Dieterici's second degree formula for c. The entropy of evaporation in column twelve is L/T. Column thirteen is the sum of columns eleven and twelve.

In all these cases, the required quantities were computed (usually to at least one extra significant figure) for each of a suitably selected set of standard pressures or temperatures, and the intermediate values filled in by interpolations involving, at times, differences of orders as high as the fifth. For such quantities as u and v, the interpolation is easier and more accurate if log u and log v are used instead of the quantities themselves.

In Table 3, the total heat and entropy increments from saturation at a number of standard pressures were computed by step by step numerical integrations of the C_p curves and the results plotted on a large scale. Smooth curves were then drawn for each of the superheats required and the increments read off for the intermediate pressures. A similar process was carried through for the specific volumes.

Since Holborn and Henning's observations on the C_p of superheated steam at atmospheric pressure run to very high temperatures, and since the spacing of the C_p curves for higher pressures is no more uncertain at 2000° superheat than at 600° superheat, it is possible to carry Table 3 to extremely high superheats with an accuracy limited chiefly by the errors already present below 600°. This has been done for several typical pressures in Table 4, and similar values for intermediate pressures can be obtained by interpolation.

The final values in all of the tables have been checked by the method of differences, by an independent computer, and as an additional precaution, many well-scattered numbers have been recomputed from the original formulæ by still another person not otherwise connected with the work. The authors will be glad to receive information as to any errors that may be discovered.
